Intracellular targeting is essential for the efficient delivery of drugs and nanotherapeutics. Transporting nanomaterials into cells' cytoplasm for therapeutic purposes can be challenging due to the endosomal trap and lysosomal degradation of cargo. To overcome this issue, we utilized chemical synthesis to design a functional carrier that can escape the endosome and deliver biological materials into the cytoplasm. We synthesized a thiol-sensitive maleimide linker that connects the well-known mitochondria targeting lipophilic triphenylphosphonium cation (TPP) to the surface of a proteinaceous nanoparticle based on the engineered virus-like particle (VLP) Qβ. TPP facilitates endosomal escape by its lipophilic and cationic nature, which disrupts the endosomal membrane. Once in the cytosol, glutathione reacts with the thiol-sensitive maleimide linkers, severs the TPP from the nanoparticle, halting its trafficking to the mitochondria, and marooning it in the cytosol. We successfully demonstrated cytosolic delivery of a VLP loaded with Green Fluorescent Protein (GFP) *in vitro* and small-ultrared fluorescent protein (smURFP) *in vivo*, where evenly distributed fluorescence is observed in A549 human lung adenocarcinoma cells and the epithelial cells of BALB/c mice lungs. As a proof of concept, we encapsulated luciferase-targeted siRNA (siLuc) inside the VLP decorated with the maleimide-TPP (M-TPP) linker. We observed enhanced luminescence silencing in luciferase-expressing HeLa cells using our sheddable TPP linker compared to control VLPs.

## Introduction

In order for medicine to be effective in diagnosing and treating diseases, such as cancer, genetic disorders, Alzheimer's, and Parkinson's, access to the cell cytoplasm is crucial.<sup>1–4</sup> Cytosolic delivery of nanomaterials and biomacromolecules is fraught with biological barriers—the largest being endosomal escape.<sup>5</sup> There are few entry routes for large or charged macromolecules aside from endocytosis. Once inside the cell endosome, the most likely outcome is eventual lysosomal degradation resulting in a low delivery dose, poor bioavailability, and limited therapeutic efficiency. This limitation has presented itself as a

significant challenge, specifically in the cytosolic delivery of large and charged therapeutic cargos and targeted delivery of drugs into the intracellular compartment. Therefore, a delivery system capable of escaping the endosome before lysosomal degradation is needed. Some available delivery systems, including hydrogels,<sup>6</sup> lipid nanoparticles,<sup>7</sup> cell-penetrating peptides,<sup>8</sup> DNA-binding protein nanocages,<sup>9</sup> and metal-organic frameworks,<sup>10,11</sup> have shown potential in promoting cellular uptake, protecting cargo from enzymatic hydrolysis, and enhancing site-specific delivery. However, these systems suffer from various limitations, including leakage of encapsulated cargo, toxicity, and inefficient delivery that results in low bioavailability. Using chemistry to address biological needs has facilitated advances in research areas such as drug discovery, bioconjugations, and materials science to improve biotherapeutic modalities.<sup>12</sup> This work uses synthetic strategies and methodologies to design a functional carrier that helps biological materials escape the endosome and reach the cell's cytosol. For this purpose, we combined maleimide (M) and triphenylphosphonium (TPP) chemistries to create this function.

The small lipophilic cationic molecule, TPP, has been long exploited as a mitochondrial targeting moiety for small and medium-sized molecules.<sup>13,14</sup> Cargo tagged with a TPP moiety

‡ These authors contributed equally to the article.

can escape the endosome and preferentially bind to the negatively charged mitochondrial matrix.<sup>15–17</sup> We wondered if we could promote endosomal escape yet avoid mitochondrial targeting by installing a linker between the nanoparticle and the TPP moiety that degrades once the nanoparticle enters the cytoplasm. TPP is an easily synthesized small molecule with low toxicity and can be chemically functionalized to a wide range of nanoparticle platforms. This gives our approach a distinct advantage over peptides, which are more costly, more complicated to attach to surfaces, and susceptible to enzymatic degradation.

We employed a proteinaceous nanoparticle called a virus-like particle (VLP) to demonstrate our approach. VLPs have emerged as a promising platform for various therapeutic applications ranging from imaging, gene delivery, and drug delivery.<sup>18–22</sup> They are non-infectious, biocompatible, biodegradable, monodisperse, and robust platforms that can carry small molecules,<sup>23,24</sup> polymers,<sup>25</sup> gold nanoparticles,<sup>26,27</sup> and/or intact proteins either by supramolecular entrapment within their interior or by chemical conjugation to their surface.<sup>28,29</sup> The bacteriophage Q $\beta$  is a 28 nm icosahedral engineered VLP with 180 identical coat proteins (CPs) that self-assembles around random mRNA during expression in *E. coli*.<sup>29–33</sup> We, and others, have shown that the CPs of Q $\beta$  can be disassembled, the random mRNA discarded, and then reassembled around new cargo or genetic material.<sup>31,33,34</sup> Furthermore, Q $\beta$  possesses functionalizable primary amine groups on three surface-exposed lysine residues (K2, K13, and K16) and the N-terminus (Scheme 1) as well as 180 solvent-exposed disulfide groups that crosslink either six or five proteins to form hexameric (Scheme 1A) and pentameric subunits, respectively. These disulfides can be reduced (Scheme 1B), and the free sulfhydryl groups are effectively “rebridged” in quantitative yields using a maleimide crosslinker (Scheme 1C).<sup>23,35</sup>

This work demonstrates a “shedtable” cytosolic delivery approach by attaching a TPP-containing moiety through a disulfide-bridging maleimide that forms a stable two-carbon bridge between the sulfurs. The maleimide on the VLP readily undergoes retro-Michael additions in the presence of glutathione (Scheme 1D), which is present in millimolar concentrations ( $10^{-3}$  M) in the cytosol but micromolar concentrations ( $10^{-6}$  M) outside the cell.<sup>36,37</sup> *In vitro*, the TPP-functionalized virus undergoes endocytosis, escapes the endosome, and then sheds the TPP-functionalized maleimide linker through a thiol exchange with glutathione in the cytosol. Moreover, we have developed a single-pot approach that allows us to simultaneously reassemble the virus around genetic cargo with a functionalized dibromomaleimide serving to ‘sew up’ the capsid.<sup>35</sup> Finally, as proof of principle, we demonstrate the cytosolic delivery of Q $\beta$  loaded with GFP *in vivo* and, in a second example, the *in vitro* cytosolic delivery of siRNA that stops luciferase expression.

## Experimental

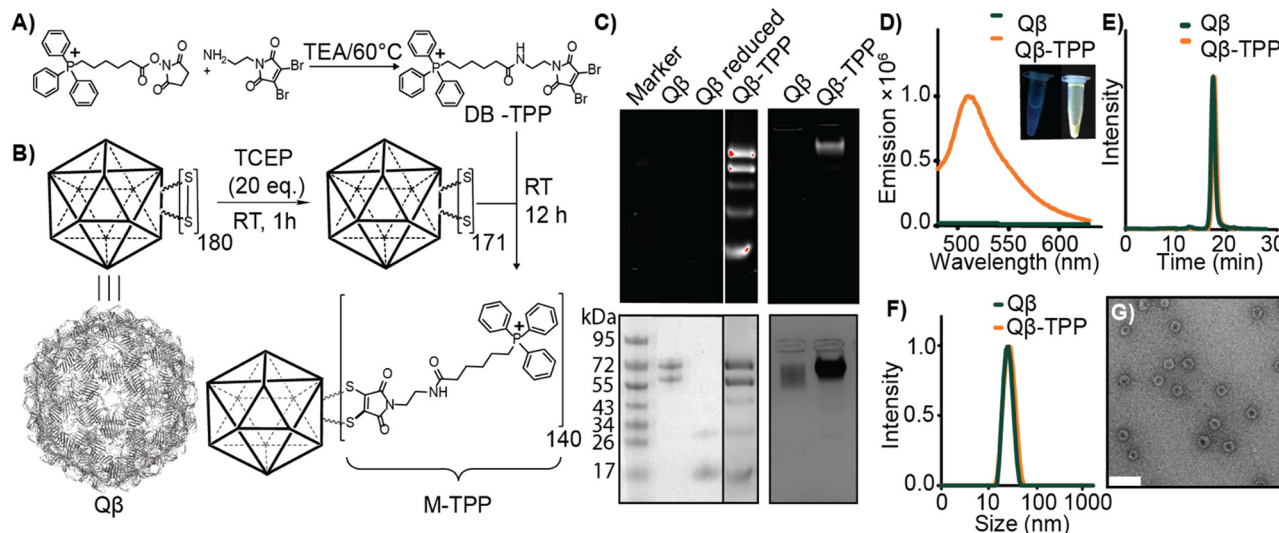

### Synthesis and characterization of Q $\beta$ -M-TPP

TPP has a delocalized positive charge over large hydrophobic phenyl rings, which is known to permeate lipid bilayers and

**Scheme 1** Structure of Q $\beta$  VLP (exposed lysines are labeled in blue, and cysteines are labeled in yellow). Hexameric and pentameric structures are colored green and orange, respectively. (A) Close-up of one of the hexameric disulfide-lined pores. (B) The disulfides can be reduced quantitatively to produce free sulfhydryl groups. (C) These can be crosslinked using a dibromomaleimide reagent. (D) The maleimide crosslinkers come off in the presence of glutathione to produce 12 free thiols.

cross into the mitochondrial matrix through non-carrier-mediated transport because of the significant mitochondrial membrane potential.<sup>12,37–41</sup> Our approach involves chemically modifying the surface of the engineered VLP Q $\beta$  using a synthetic linker that separates the TPP from the viral surface once the capsid enters the cytosol. We prepared a dibromomaleimide-triphenylphosphonium (DB-TPP) linker (Fig. 1A and B) *via* direct EDC coupling. The dibromomaleimide moiety reacts with thiol groups in a two-step reaction,<sup>42</sup> each step having a half-life of seconds.<sup>35,43</sup> Q $\beta$  contains 180 disulfide bonds, each of which can be a potential site for functionalization *via* this approach. The attachment of DB-TPP to Q $\beta$  forms a covalent two-carbon “bridge” between the free thiol groups in reduced Q $\beta$  (Fig. 1B).<sup>43,44</sup> First, Q $\beta$  is reduced using tris(2-carboxyethyl) phosphine (TCEP), which is confirmed by electrophoretic mobility in non-reducing 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The starting Q $\beta$  pentameric and hexameric subunit bands are shown in Fig. 1C, which are converted almost exclusively into monomer bands following reduction. Ellman’s assay further confirms reduction against a cysteine standard curve (Fig. S1, ESI $^{\dagger}$ ), where approximately 95% of the disulfides on Q $\beta$  were found to be reduced into free thiols. The bioconjugation was then completed following the addition of the DB-TPP molecule, and within a few minutes, conjugation was confirmed by a significant visible increase in yellow-green fluorescence under UV light. Electrophoretic mobility using non-reducing 10% SDS-PAGE (Fig. 1C) shows the reformation of the hexameric and pentameric subunits and a slight upward migration of these bands compared to unreduced

**Fig. 1** (A) Synthesis of dibromomaleimide-TPP (DB-TPP) linker followed by (B) bioconjugation strategy on Q $\beta$ . (C) Electrophoretic mobility analyses of Q $\beta$  before and after DB-TPP conjugation using 10% SDS-PAGE (left) and 1% agarose (right) gels showing successful bioconjugation of the maleimide linker to Q $\beta$ , forming Q $\beta$ -M-TPP. SDS-PAGE shows the successful reduction of the higher-order structures and their reappearance after conjugating DB-TPP. The fluorescence imaging of agarose (top right) shows the maleimide fluorescence at the same spot of the Coomassie-stained band. (D) Fluorescence spectra of Q $\beta$ -M-TPP and Q $\beta$  before and after conjugation with DB-TPP (ex/em 400/540 nm) with a photograph showing the reaction mixtures of Q $\beta$ -M-TPP under 365 nm UV lamp illumination. (E) SEC of Q $\beta$ -M-TPP and Q $\beta$ . After bioconjugation, (F) DLS and (G) TEM of Q $\beta$ -M-TPP show no aggregation or structural change. Scale bar = 100 nm.

Q $\beta$ . These bands are also fluorescent under UV light, providing further evidence for the successful conjugation of the maleimide-TPP (M-TPP) linker to Q $\beta$ . Native agarose electrophoresis of the conjugate, visualized by UV and Coomassie staining, shows less migration toward the positive electrode than unfunctionalized Q $\beta$ , which is attributed to the additional positive charge from the TPP moiety. Intensity from the newly formed Q $\beta$  M-TPP conjugate (Q $\beta$ -M-TPP) can be measured by fluorescence spectroscopy at 540 nm (excitation 400 nm) (Fig. 1D).<sup>35</sup> This emergence of yellow fluorescence following the successful displacement of the bromides and formation of the dithiolated conjugate has been attributed to lower self-quenching and a decrease in the frequency of emission-decreasing collisional events with solvent molecules following conjugation.<sup>35,44</sup> We found no changes in the size of Q $\beta$ -M-TPP compared to Q $\beta$  as determined by size exclusion chromatography (SEC) and dynamic light scattering (DLS) analyses (Fig. 1E and F) – Q $\beta$  and Q $\beta$ -M-TPP have hydrodynamic radii ( $R_h$ ) of  $31.92 \pm 10.76$  and  $31.22 \pm 10.36$  nm respectively. Transmission electron microscopy (TEM) confirms that the morphology of conjugated Q $\beta$ -M-TPP is unchanged (Fig. 1G).  $\zeta$ -potential measurements show an increase in positive charge on Q $\beta$  after conjugation, which arises from the cationic nature of TPP (Fig. S2, ESI $^\dagger$ ). Lastly, the total number of conjugated linkers per capsid was determined to be approximately 140 linkers (78% of surface disulfide bonds) per Q $\beta$  by Ellman's assay (Fig. S1, ESI $^\dagger$ ). Glutathione (GSH) tripeptide is the most abundant thiol species in the cytosol of living cells and acts as a biological reducing agent. The intracellular concentration of GSH is (1–10 mM), whereas the concentration drops to about 1–10  $\mu$ M in extracellular matrices.<sup>45,46</sup> Therefore, the cytosol of mammalian cells contains 100–1000 times the amount of GSH compared to the extracellular

compartment creating a thiol-rich environment. This environment presents a unique opportunity for cargo's specific and selective cytosolic release *via* a thiol exchange reaction with our disulfide-linker on Q $\beta$ . We hypothesized that the Q $\beta$ -M-TPP formulation, with its thiol-maleimide bonds, will undergo retro-Michael additions with the abundant GSH, separating most of the TPP from the VLP surface and forming GSH-M-TPP. To verify this supposition, we labeled dibromomaleimide with the small fluorescent molecule FITC (Fig. S3, ESI $^\dagger$ ) and did an *ex vitro* thiol-exchange experiment by subjecting the Q $\beta$ -M-FITC conjugate to conditions that would approximate the cytoplasm (20 mM HEPES, 100 mM KCl, 1 mM MgCl<sub>2</sub>, 1 mM EDTA, 1 mM glutathione, pH 7.4, 37 °C).<sup>44,47</sup> Scrambling of M-FITC linker from Q $\beta$  onto GSH was analyzed using SEC. As expected, data shown in Fig. S4 (ESI $^\dagger$ ) indicates cleavage of the M-FITC linker from Q $\beta$  and attachment to GSH. The starting retention time of Q $\beta$ -M-FITC is 16.8 min in the SEC trace. After 24 h, however, we observed the formation of new FITC-labeled oligomers of GSH with lower MW compared to Q $\beta$ , having retention times of 21.3 and 27.9 min. We note that there is still Q $\beta$ -M-FITC after 24 h, though the peak height decreased about 61% over 24 h. This observation suggests such conjugates have the potential to cleave in the cytosol of cells; however, to determine if the amount of cleavage was sufficient, we moved to *in vitro* experiments.

## Results and discussion

### Cellular uptake, cytotoxicity, and delivery of Q $\beta$ -M-TPP

We next moved to *in vitro* studies of the conjugates. Human lung cancer is one of the fastest-growing malignant tumors,

and its treatment is limited by intrinsic resistance to certain anticancer drugs, that exert their therapeutic effect within the cell's cytoplasm. For *in vitro* studies, non-small cell lung cancer (NSCLC) A549 human adenocarcinoma lung cells were employed to evaluate the cell viability, cellular uptake, and cytosolic delivery following treatment with the designed formulation. To visualize the protein trafficking into and throughout the cell, we used fluorescently engineered Q $\beta$  that contains Green Fluorescent Protein within the viral capsid—Q $\beta$ (GFP).<sup>48</sup> The viability of A549 cells following different treatments with Q $\beta$ (GFP) and Q $\beta$ (GFP)-M-TPP was measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and compared to that of untreated controls. As shown in Fig. 2A, we found exceptionally low toxicity, even at high concentrations, with cell viabilities more significant than 97% following exposure to each formulation at a 2 mg mL<sup>-1</sup> concentration after a 4 h incubation. These results indicate that the Q $\beta$  particles decorated with M-TPP should have high biocompatibility and low toxicity. Next, we treated cells with Q $\beta$ (GFP) or Q $\beta$ (GFP)-M-TPP and quantified cellular uptake with flow cytometry after fixing the cells. We observed a slight increase in uptake in cells treated with Q $\beta$ (GFP)-M-TPP, as compared to Q $\beta$ (GFP), which suggests modifying Q $\beta$  with the linker does not significantly affect particle uptake (Fig. 2B). We next used fluorescence microscopy to visualize uptake and cytosolic delivery of Q $\beta$ (GFP)-M-TPP in fixed A549 cells. The obtained images revealed that the delivered Q $\beta$ (GFP)-M-TPP was evenly distributed as green fluorescence throughout the cytosol (Fig. 2D) while Q $\beta$ (GFP) shows punctate fluorescence dots that indicate endosomal entrapment (Fig. 2C). We also tested the cytosolic delivery of Q $\beta$ (GFP)-M-TPP *vs.* Q $\beta$ (GFP) in live A549 cells as shown in Fig. S5A (ESI<sup>†</sup>). In the live-cell imaging studies, we observed the same results as in fixed cells. The Q $\beta$ (GFP)-M-TPP green fluorescence was diffuse in the cells, proving the ability of Q $\beta$ (GFP)-M-TPP to escape the endosome and reach the cytosol; however, we saw very little green fluorescence in live cells treated with Q $\beta$ (GFP) because it was quenched from the acidic environment of the endosome.<sup>32,48</sup> The live cells were stained with LysoTracker and nuclear stain Hoescht dye, as shown in Fig. S6 and S7 (ESI<sup>†</sup>). Furthermore, to emphasize that TPP does not deliver Q $\beta$ (GFP) to the mitochondria because of cytosolic cleavage, the treated and fixed cells were stained with MitoTracker™ Deep Red FM. As shown in Fig. 2E and F, there is no overlap between the red fluorescence of MitoTracker and the green fluorescence of Q $\beta$ (GFP).

We then progressed to the *in vivo* evaluation of our Q $\beta$  system. To overcome the autofluorescence of lung tissue, which fluoresces in the GFP channel, we used a genetically modified Q $\beta$  expressing small Ultra-Red Fluorescent Protein (smURFP), smURFP@Q $\beta$ , which we have previously shown to overcome the ambiguities of imaging in highly autofluorescent tissues.<sup>49</sup> smURFP@Q $\beta$ -M-TPP was attached using the same methods as our GFP variant (Fig. S8, ESI<sup>†</sup>) and the fluorescent protein did not seem to influence the bioconjugation chemistry. Mice were administered three doses of 2 mg mL<sup>-1</sup> smURFP@Q $\beta$  or smURFP@Q $\beta$ -M-TPP through intratracheal lung lavage. After 6 h, their lungs were collected and processed for confocal

Fig. 2 (A) Cell viability of A549 lung cancer cells after treatment with Q $\beta$ (GFP) and Q $\beta$ (GFP)-M-TPP (2 mg mL<sup>-1</sup>) for 4 h at 37 °C. (B) Flow cytometry was used to assess the uptake of Q $\beta$ (GFP)-M-TPP and Q $\beta$ (GFP) (2 mg mL<sup>-1</sup>) in fixed A549 cells after incubation at 37 °C for 4 h. (C) Fluorescence microscopy images of fixed A549 cells treated with Q $\beta$ (GFP) showing punctate dots coming from endocytic uptake and A549 cells treated with (D) Q $\beta$ (GFP)-M-TPP showing diffuse green fluorescence related to the cytosolic release of Q $\beta$ (GFP). Color code: green: Q $\beta$ (GFP). Scale bar = 50  $\mu$ m. (E) Fluorescence micrograph of Q $\beta$ (GFP) and (F) Q $\beta$ (GFP)-M-TPP in fixed A549 cells stained with MitoTracker showing no mitochondrial colocalization of Q $\beta$ (GFP)-M-TPP. Color code: red: MitoTracker Deep Red FM and green: Q $\beta$ (GFP). Scale bar = 50  $\mu$ m. (G) Fluorescence microscopy images of *ex vivo* lung cells smURFP@Q $\beta$  in endosomal traps, observed by bright localized fluorescence, and (H) enhanced delivery of smURFP@Q $\beta$ -M-TPP conjugates to the cytosol of cells indicated by diffuse magenta fluorescence. Color code: blue: DAPI and magenta: smURFP@Q $\beta$ . Scale bar = 50  $\mu$ m.

microscopy. Without the M-TPP linker, magenta fluorescence from the smURFP@Q $\beta$  appears localized within pockets (Fig. 2G) around the cells. We could not determine where the VLP was localized in the lung tissue, but it seemed clear that it was not in the cytosol. However, with the endosome-escaping linker, more overlap of smURFP fluorescence was observed diffusely in the tissue (Fig. 2H), suggesting that delivery of smURFP@Q $\beta$ -M-TPP

was to the cytosol of the cells. Since the fluorescence is so diffuse throughout the cells, we believe that our linker conjugates allowed for the evasion of endosomal trapping and lysosome degradation of smURFP@Q $\beta$ .

To further prove the role of the intermediate linker in thiol exchange cleavage and cytosolic delivery, we labeled the lysine residues of Q $\beta$  with TPP using a non-cleavable linker.<sup>13</sup> We expected that functionalizing the Q $\beta$  surface with TPP without a cleavable linkage would traffic our carrier, Q $\beta$ , to the mitochondria. To test this, we covalently attached the TPP to the free amine groups on the surface of Q $\beta$  through NHS ester chemistry (Fig. 3A).<sup>50</sup>

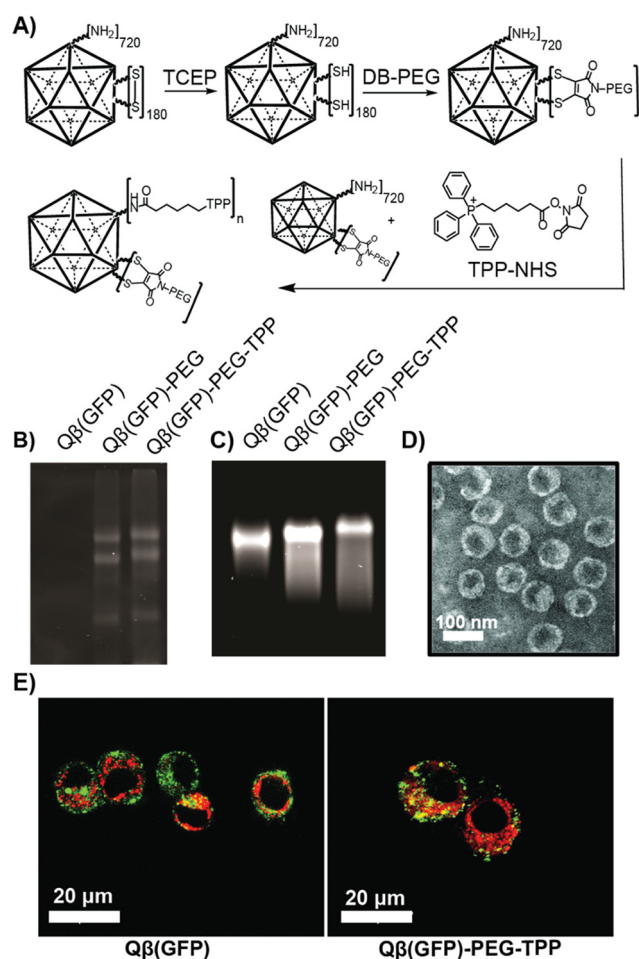

Curiously, unlike the attachment at the disulfides, this functionalization resulted in a sensitivity of the Q $\beta$  towards ions in the buffer and poor colloidal stability and precipitation

when preparing the sample in cell media (DMEM) for *in vitro* studies. Efforts to control this by reducing the number of TPP molecules to a relative minimum were only modestly successful. We previously found that attaching lipophilic drug molecules to the Q $\beta$  lysines creates problems for colloidal stability. By attaching polyethylene glycol (PEG) linkers across the disulfides, we could significantly increase the solubility and stability of the Q $\beta$ .<sup>51</sup> Here, we applied the same strategy and first decorated Q $\beta$  with dibromomaleimide-PEG at the reduced disulfide bonds, followed by the attachment of TPP moieties to the free lysines. Bioconjugation conditions were optimized, and particle size, surface charge, and morphology before and after conjugation were characterized, as shown in Fig. 3B–D. The mitochondria-targeting of Q $\beta$ -M-TPP was assessed *in vitro* on another common drug-resistant non-small cell lung cancer cell model H2073 by confocal fluorescence microscopy. Cells treated with Q $\beta$ (GFP)-M-TPP and stained with MitoTracker Deep Red FM were used to determine the colocalization of the green fluorescence of Q $\beta$ (GFP) conjugates with the mitochondria (Fig. 3E). Colocalization was calculated using Pearson's coefficient ( $\rho$ ) and NIH ImageJ. From the results, the targeted conjugates show greater colocalization with MitoTracker ( $\rho = 0.56$ ) than the non-targeted conjugates ( $\rho = 0.28$ ), suggesting modest colocalization within the mitochondria. Notably, a significant number of particles were still observed in the endosome/lysosome (punctate dots), but there was no diffuse fluorescence indicative of cytosolic delivery.

#### Delivery of siRNA to efficiently silence luciferase *in vitro*

Proving delivery into the cytosol using optical microscopy can be ambiguous. Thus, to further verify cytosolic entry and check the applicability of our delivery system, we used Q $\beta$ -M-TPP to deliver luciferase-targeted siRNA (siLuc), an siRNA (small-interfering RNA) probe capable of silencing luciferase expression in HeLa luciferase cells.<sup>52</sup> This work aims to demonstrate the cytosolic delivery of a VLP; proving its capability to enhance siRNA delivery compared to existing transfection agents is beyond the scope of this paper. With that said, siRNA is not only a useful *in vitro* tool, it is also a powerful therapeutic tool that inhibits specific messenger RNA (mRNA) expression in the cytosol and effectively downregulates the gene expression processes.<sup>53</sup> However, siRNA is highly anionic, has a relatively large molecular weight, and quickly degrades in cell media. Naked siRNA cannot readily penetrate cell membranes and reach the cytoplasm; therefore, we hypothesized that encapsulation of siRNA in Q $\beta$ -M-TPP could enhance cytosolic delivery and improve gene silencing compared to free siRNA or Q $\beta$  that lacked cleavable TPP groups.

Q $\beta$  capsid formation occurs in the recombinant *E. coli* expression system through charge-mediated interactions between the negatively charged random *E. coli* RNA and positively charged Q $\beta$  CP subunits.<sup>34,54</sup> Disulfide formation in the biological synthesis of Q $\beta$  occurs after the capsid has self-assembled, likely following exposure to molecular oxygen in the bacteria or following cell lysis. Given the highly negative charge of siRNA,<sup>55</sup> we hypothesized siLuc could promote assembly of Q $\beta$  capsids and addition of the

**Fig. 3** (A) Conjugation scheme of Q $\beta$ -PEG-TPP. Q $\beta$  first is reduced with TCEP, followed by adding Dibromomaleimide-PEG (DB-PEG). Conjugation of TPP-NHS with surface amines is then performed using TPP-NHS. Characterization of Q $\beta$ -PEG-TPP conjugation (B) 10% SDS gel (C) 1% agarose gel (D) TEM (scale bar: 100 nm). (E) Fluorescence micrographs of NSCLC H2073 cells treated with Q $\beta$ (GFP) and Q $\beta$ (GFP)-PEG-TPP. Q $\beta$ (GFP)-PEG-TPP is driven into the mitochondria with greater colocalization efficiency ( $\rho$ ), which is calculated using Pearson's coefficient, colocalization ( $\rho = 0.56$ ) compared to non-targeted conjugates ( $\rho = 0.28$ ). Color code: green: Q $\beta$ (GFP), red: MitoTracker Deep Red FM.

Fig. 4 (A) Scheme for disassembly of Q $\beta$  virions to CPs, then the reassembly around siRNAs to make siRNA@Q $\beta$ -M-TPP. (B) Cell viability and (C) relative levels of luciferase expression in HeLa luciferase cells after various treatments.

DB-TPP could “sew” the capsid up in a one-pot process. Specifically, we anticipated that we could reduce the Q $\beta$  with 1,4-dithioerithrol (DTT) and disassemble the capsid in a salt solution. The addition of siLuc could then promote capsid reassembly, and DB-TPP could seal the capsid *in situ* as the last step (Fig. 4A).

First, purified Q $\beta$  VLPs were disassembled into CPs through a salt-controlled disassembly method<sup>16,32</sup> by adding the reducing agent DTT and magnesium chloride (MgCl<sub>2</sub>), which facilitates the recovery and precipitation of packed RNA. Next, the obtained CP was purified using dialysis and centrifugation. SEC, 1% agarose, and 10% SDS gel electrophoresis were used to verify the *E. Coli* RNA was removed and the Q $\beta$  disassembled into CPs (Fig. S9, ESI<sup>†</sup>). Data show the presence of CPs through a single band in SDS-PAGE and positive charge migration through agarose gel electrophoresis with a change in capsid retention time by SEC. Reassembly proceeded in the presence of siRNA under DTT-reducing conditions. We found that a siRNA to CP ratio of 1:4 was sufficient to promote complete capsid formation.

Finally, we proceeded with the surface installation of TPP directly in the reassembly buffer by adding 50 eq. of DB-TPP to

the solution. Absorbance at A260/280 ratio was used to confirm complete siLuc packing. We were happy to find that the A260/280 ratio increased from 0.87 (pre-siLuc packing) to 2.0 (post-siLuc packing). Direct observation of the VLP assemblies was done by TEM. Fig. S10 (ESI<sup>†</sup>) shows well-formed VLPs after the encapsidation of the siRNA, which is further confirmed by 1% agarose and 10% SDS gel electrophoresis showing the hexameric and pentameric subunits of siRNA@Q $\beta$ -M-TPP exhibiting similar integrity to native Q $\beta$  (Fig. S10, ESI<sup>†</sup>). To assess the *in vitro* cytosolic delivery of siRNA using siRNA@Q $\beta$ -M-TPP, we compared the silencing ability of naked siRNA, siRNA loaded in Q $\beta$  without the M-TPP linker, and siRNA loaded in Q $\beta$ -M-TPP in luciferase-expressing HeLa cells. The cell viability and luciferase expression were measured using standard One-Glo Tox luciferase and cell viability assay. It was found that after 24 h, all treatment groups had high cell viability (Fig. 4B), but the siRNA@Q $\beta$ -M-TPP treated cells showed a significantly lower luciferase expression (47%) as compared to free siRNA treated cells (93%) (Fig. 4C). Considering that uptake of Q $\beta$  and Q $\beta$ -M-TPP are comparable, this result further proves the cytosolic delivery of our formulation and demonstrates—as a proof-of-principle—that we can enhance cytosolic siRNA delivery *via* this approach.

## Conclusions

Most nanoparticle-based delivery systems must escape the endosome and lysosome to reach the cytosol for efficient therapeutic and diagnostic action. In this work, we chemically modify the surface of an engineered protein model, Q $\beta$ , using a glutathione-sensitive linker attached to a lipophilic cation to overcome endosomal entrapment and achieve cytosolic delivery. Our approach using a “sheddable linker” was further confirmed when we observed no cytosolic delivery without a GSH cleavable linker. As proof-of-principle, we successfully demonstrate the applicability of our synthetic bioconjugation strategy in the cytosolic delivery of a VLP-carrying GFP *in vitro*, smURFP *in vivo*, and siRNA *in vitro*. Ultimately, both *in vitro* and *in vivo* studies have the potential to be useful for therapeutic and clinical applications and will be considered for future work.

## Author contributions

JJG conceived the project and wrote the manuscript with AS and LH. AS, LH, NA, AT, and HF synthesized all compounds. AS, AB, LH, and NA performed bioconjugation and characterization. AS, LH, OB, and NA conducted *in vitro* experiments and fluorescence microscopic imaging. LH, FC, and IT performed *in vivo* experiments, and LH, IT, and SC conducted confocal imaging. ZC performed PEGTPP conjugation and *in vitro* experiments. AS and FC conducted RNA encapsulation and characterization. NA duplicated the synthesis and *in vitro* work to demonstrate rigor.
